The meshing engagement of the stationary scroll and movable scroll in the chamber results in the suction of fluid from an inlet port, the compression of fluid by the stationary scroll and the discharge of fluid from an outlet port. In order to control the state of engagement between the stationary scroll and movable scroll, a fluid pressure-retaining structure is disposed in the discharge chamber. For example, Japanese Unexamined Patent Publication No. 58(1983)-8938 discloses a structure in which the discharge chamber has a fluid pressure-retaining structure which comprises a control plate formed integrally with the discharge chamber, a connection hole formed in the control plate, and a discharge hole formed in the discharge chamber and communicated with the connection hole. Further, the discharge hole is provided with a diaphragm to control the aperture size of the discharge hole. In this conventional construction, the discharge hole communicates directly with the connection hole provided in the control plate. Thus, when the discharge hole is adjusted for control by the diaphragm, the aperture of the discharge hole is also adjusted by the diaphragm. As a result, the actual aperture size of the discharge hole may not correspond to the aperture size set by the diaphragm. Thus, there is a tendency for overdischarge when the actual aperture size of the discharge hole is greater than the set aperture size. Further, this construction requires the provision of the control plate. This increases the number of component parts and the number of assembly steps

I've been reading about the multi-core CPUs and the advantages of them, but I'm confused as to why they don't get used more often. They seem to be the future of computing. What are some of the pros and cons of running on a single core CPU? Is it solely cost (which it shouldn't be, as it is less expensive)? A: I think your question is essentially the same as "Why don't manufacturers just use a single core instead of multiple cores?" But, why single? For one thing, not all task are best suited to a single thread. Web browsers run in a multithreaded environment, however, and that's not a bad fit, but there's some other issues - Firefox is a good example of a multi-threaded piece of software where memory allocation and other tasks are performed in a second thread, allowing the UI to smoothly render on screen. Can anyone say "my Task Manager shows this program using 98% of a single CPU core"? Personally, I use more than one core, but because I use virtualization, my maximum amount of virtual CPUs is 570a42141b
